

Spatial distribution of phylogenetic and trait diversity of angiosperms

Intro

- Phylogenetic study of where on earth is the early history of angiosperms disproportionately preserved?
 - I.e. where communities with longer than expected branch lengths

Intro

- How does this compare to traditional ideas about this
- Classic hypotheses
 - Traditionally focus on tropical rainforest, island environments and old geologies
 - Climatically stable ancient oceanic islands
 - New Caledonia, Madagascar, etc.
- OCBILs
 - Geologically old, climatically stable regions, with low fertility that allow for low extinction
 - South Africa, SW Australia, etc.

Intro

- Are PD &/or species richness higher in these areas
- Is the presence of plesiomorphic angiosperm traits associated with these areas?

How?

- First step – map where the early diversity of flowering plants is best preserved today
- Two ways to measure
 - Phylogenetic diversity
 - Popular modern method
 - Merge spatial and phylogenetic data, calculate one of several summary stats
 - Trait diversity
 - Often what early hypotheses referred to – plesiomorphic traits
- Wanted to assess in two ways – phylogenetic stats but traditionally morphologically conservative taxa were the focus

Biotaphy project

- Collaborative project between UF, KU, U Mich, MSU
- Preliminary analyses
- Data wrangling – linked ~40,000 SDMs with trait data, environmental predictors

Definitions

- Tip and node

Traits

- Made a list of 22 traits that
 - Are highly conserved
 - Able to be scored at the familial or ordinal levels
 - We will discuss 5: Laminar stamens, perianth phyllotaxis, stamen phyllotaxis, chloranthoid teeth, & ethereal oil cells

Traits

- Scored traits categorically as 0, 1, 2..., etc. at familial and ordinal levels
 - Traits recovered as ancestral by (Soltis et al. 2018) were assigned the “0 “ category
 - Any other number is assigned to derived states/ apomorphies
 - Traits were associated to individual taxa by GBIF backbone taxonomy

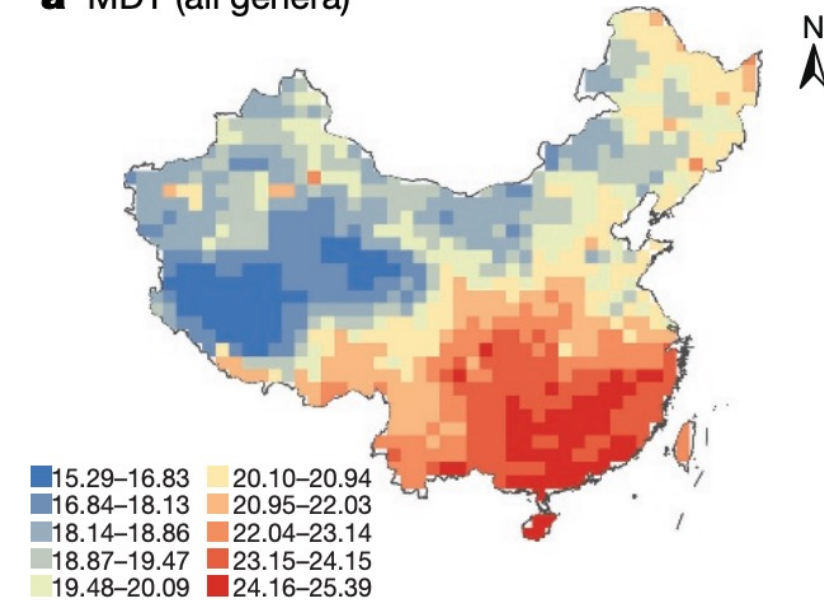

Traits

- Used these traits as a proxy for overall ancestral trait diversity
- Focused on proportion of the community with plesiomorphic traits
 - E.g. --A grid cell with 0.5 chloranthoid teeth = half of the community members in that grid cell have chloranthoid teeth
 - Considered both individual traits and means

Goals

- Determine global patterns of angiosperm community age
- Classic hypotheses about “relicts” in climatically stable island environments – Madagascar, New Caledonia
- In many respects, expanding on a recent Nature paper on the flora of China – uncovered major age gradients related to climate stability and orogeny
 - Relied heavily on taxonomic ranks

a MDT (all genera)

LETTER

doi:10.1038/nature25485

Evolutionary history of the angiosperm flora of China

Li-Min Lu^{1*}, Ling-Feng Mao^{2*}, Tuo Yang^{1*}, Jian-Fei Ye^{1,3,4*}, Bing Liu^{1,5*}, Hong-Lei Li^{6,7*}, Miao Sun^{8,9*}, Joseph T. Miller^{10,11}, Sarah Mathews¹⁰, Hai-Hua Hu^{1,3}, Yan-Ting Niu^{1,3}, Dan-Xiao Peng^{1,3}, You-Hua Chen¹², Stephen A. Smith¹³, Min Chen¹⁴, Kun-Li Xiang^{1,3}, Chi-Toan Le^{1,3}, Viet-Cuong Dang^{1,3}, An-Ming Lu¹, Pamela S. Soltis^{9§}, Douglas E. Soltis^{8,9§}, Jian-Hua Li^{15§} & Zhi-Duan Chen^{1,5§}

Tip and node ages

- Largely measure the same thing... R^2 0.6467
- Typical problem – separating species richness effects from biodiversity measures
 - Not cumulative like Faith's PD but there could still be sampling effects
 - Node height \sim species richness R^2 0.1289
 - Could include species richness as predictor to separate
 - Tip length \sim species richness R^2 0.004349, continued with this
 - Explanatory power of environmental variables was also better for tip length (with ~ 0.4 more R^2)
- Focused on tip lengths

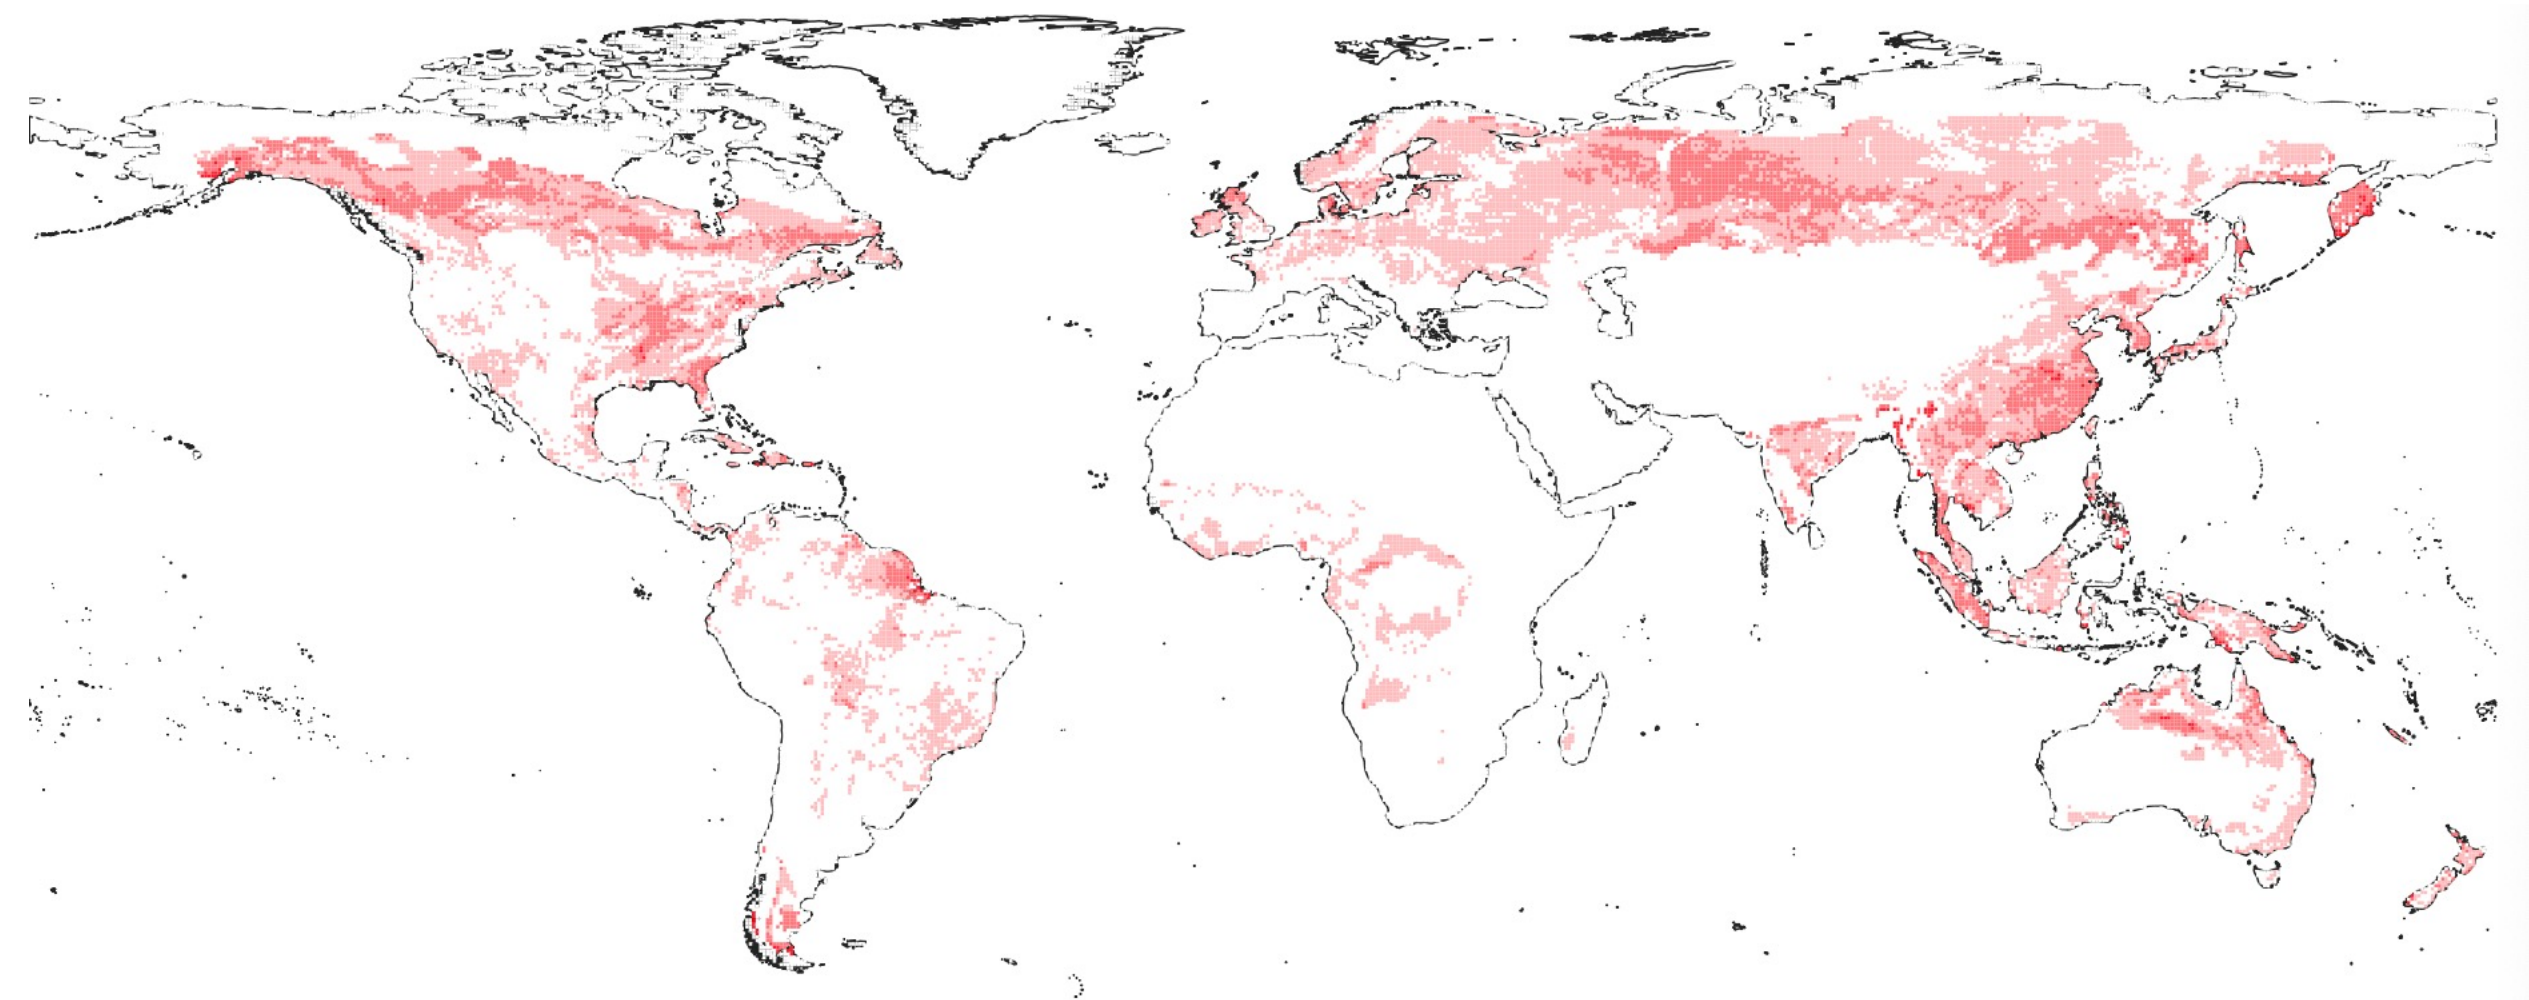

Dataset properties

- Are communities with phylogenetically old species enriched for plesiomorphic traits?
 - Plesiomorphic traits correlate weakly or not at all to phylogenetic measures of age
 - E.g., ethereal oil cells vs. mean node age, R^2 0.024

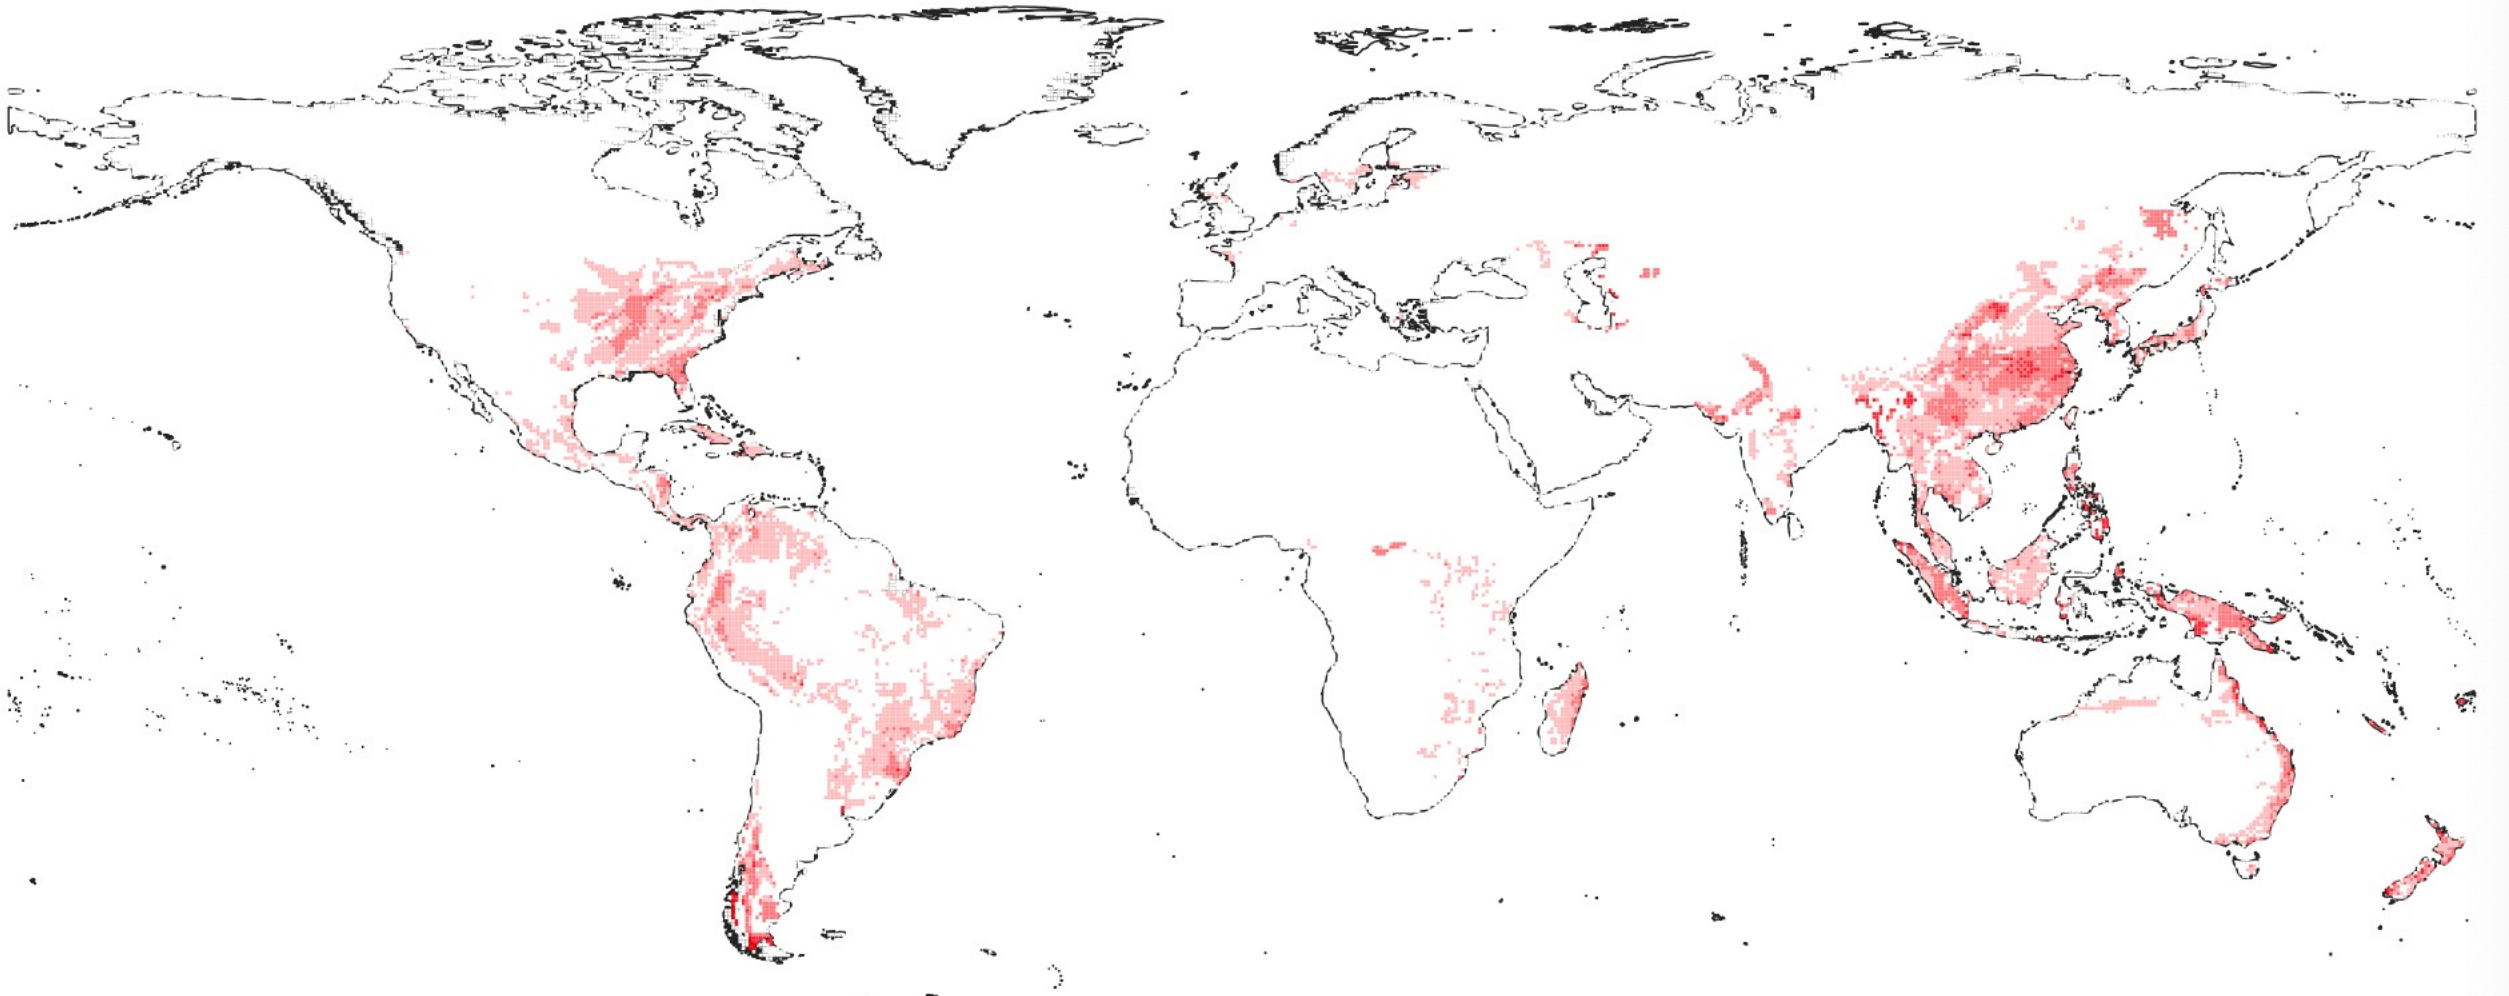

Maps of trait diversity

- Showing fractional richness of plesiomorphic trait
 - Each grid shows species richness for only taxa with the trait
- Color scale
 - Jenks natural breaks (scaling is long-tailed in many)
 - Deals with exponential and other distributions
 - Brings out contrast in the dataset
 - Scaling depends on variable (not 0% to 100%)

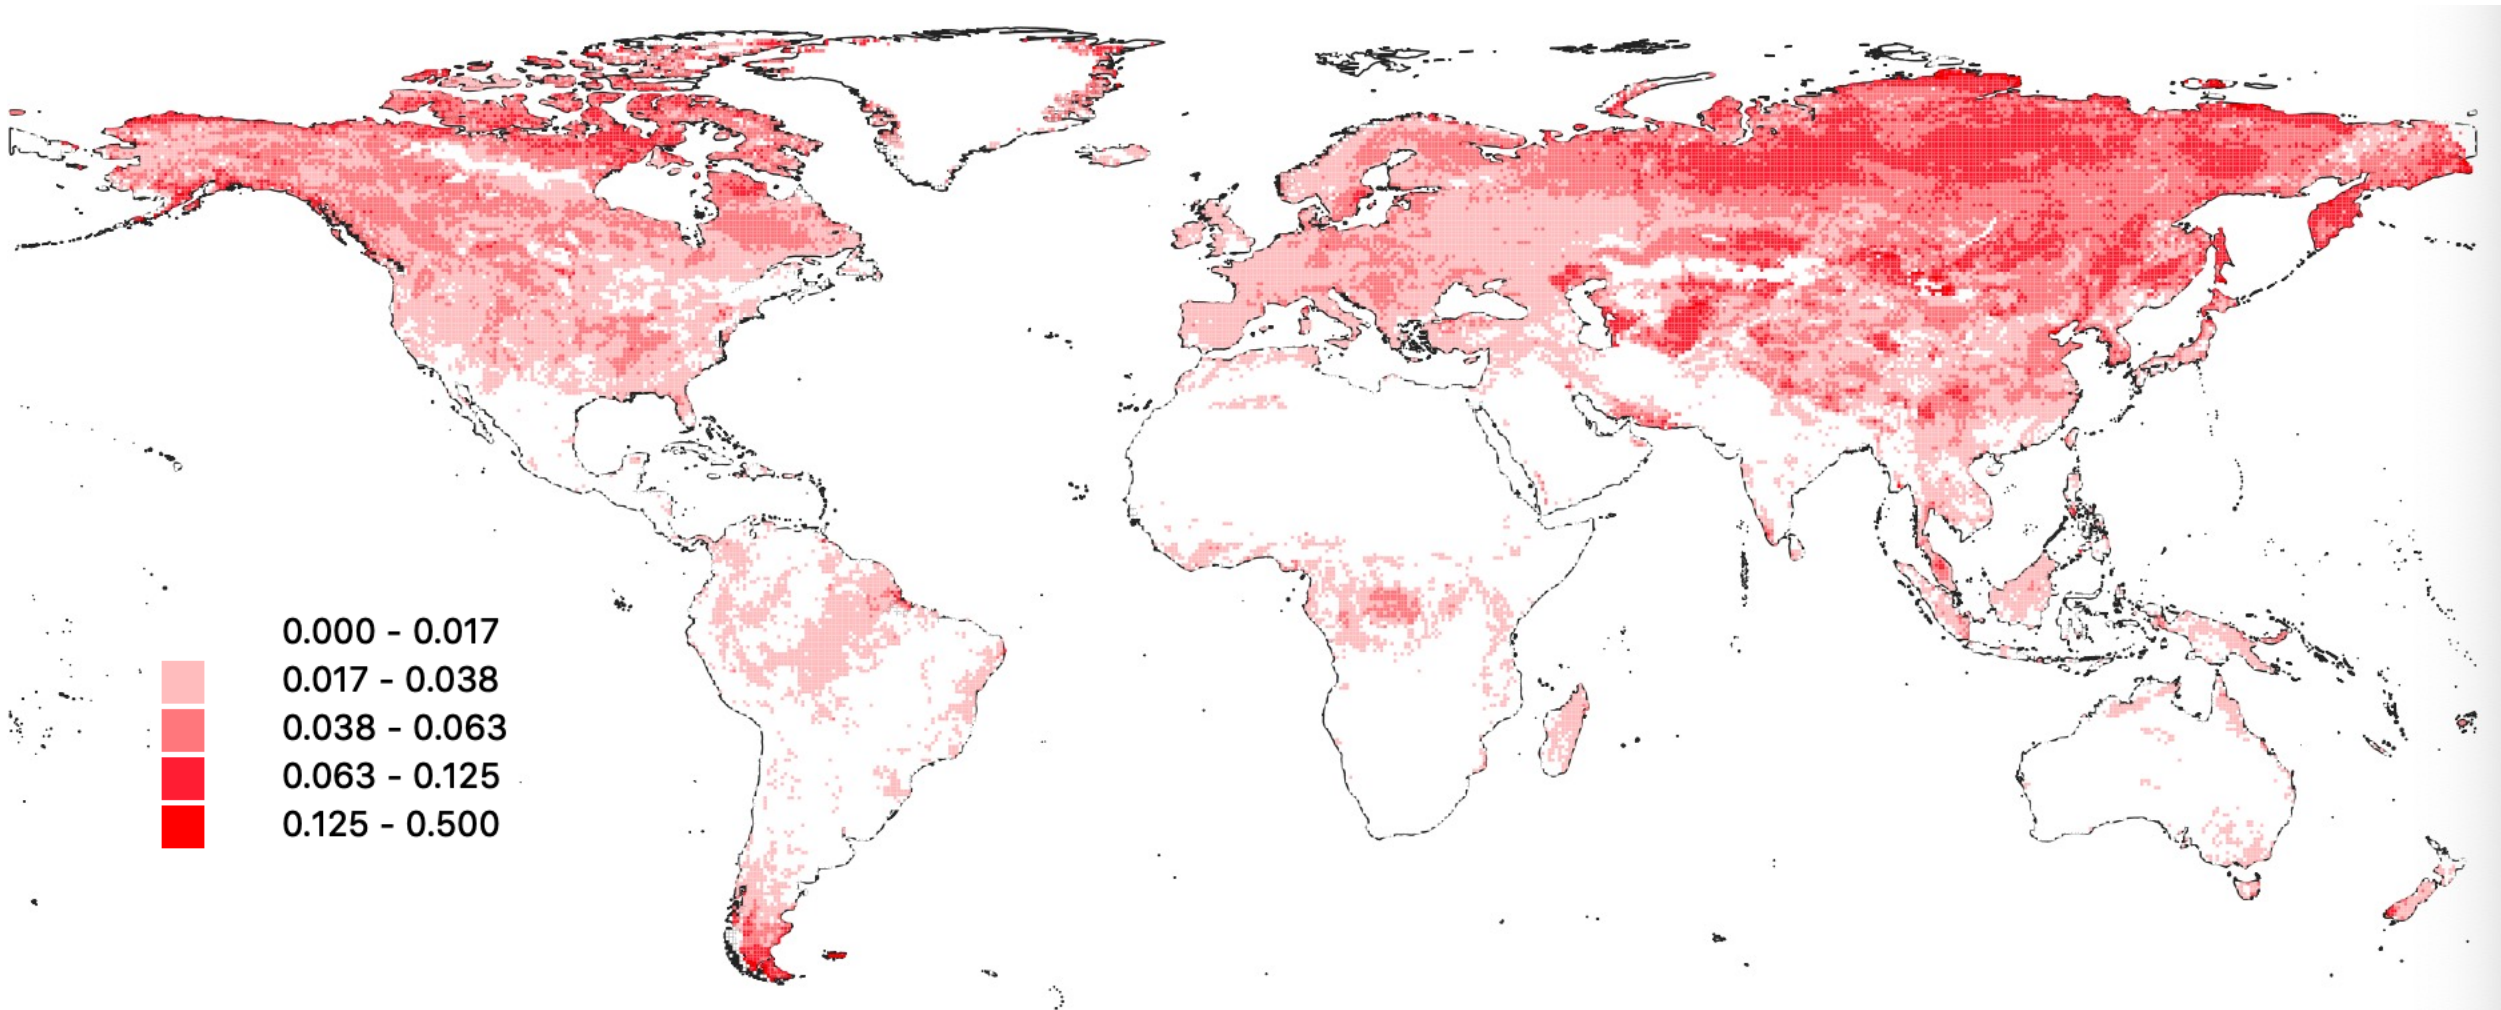

Laminar stamens

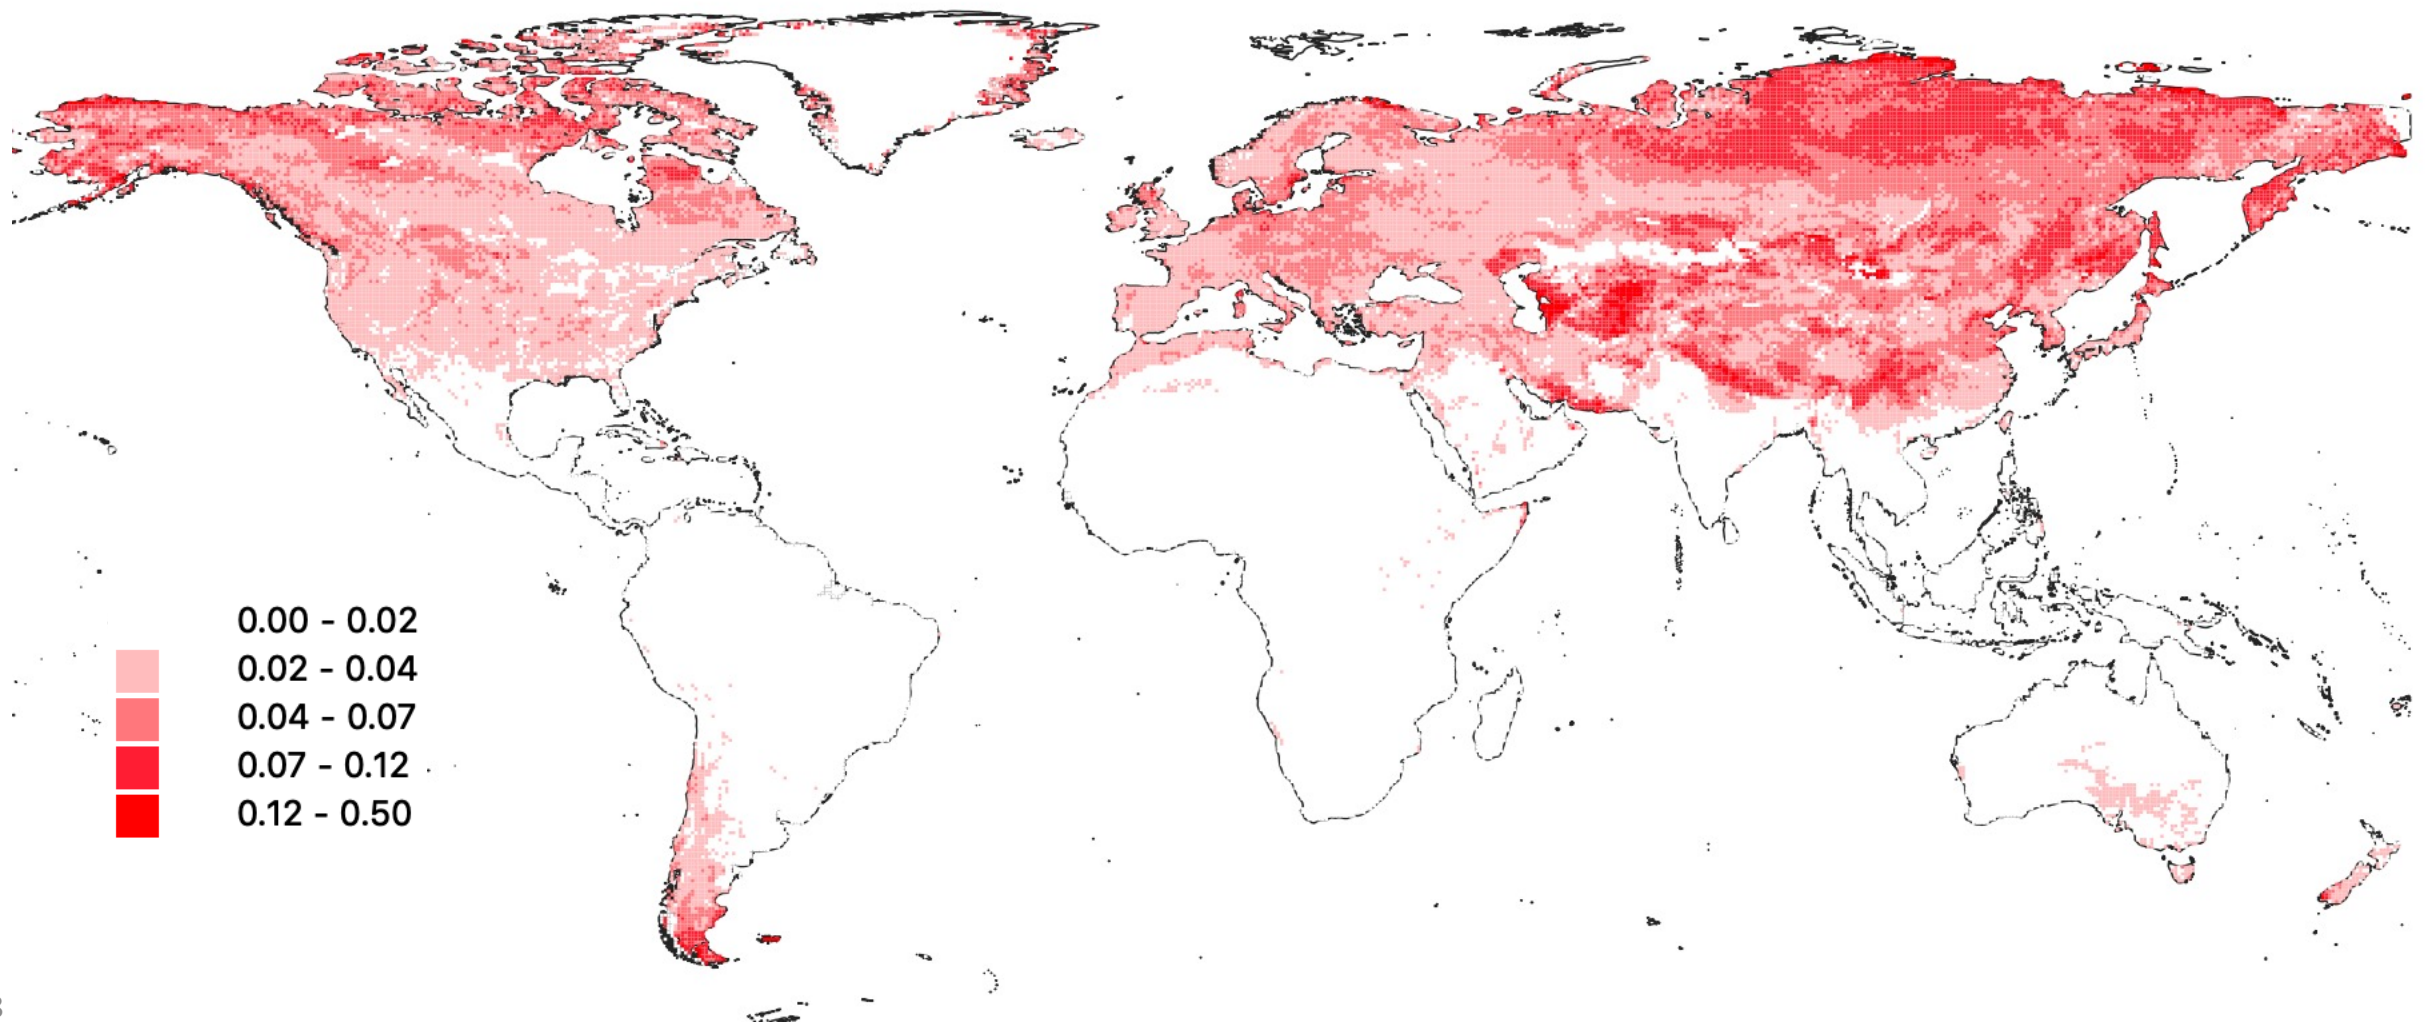

Perianth phyllotaxis

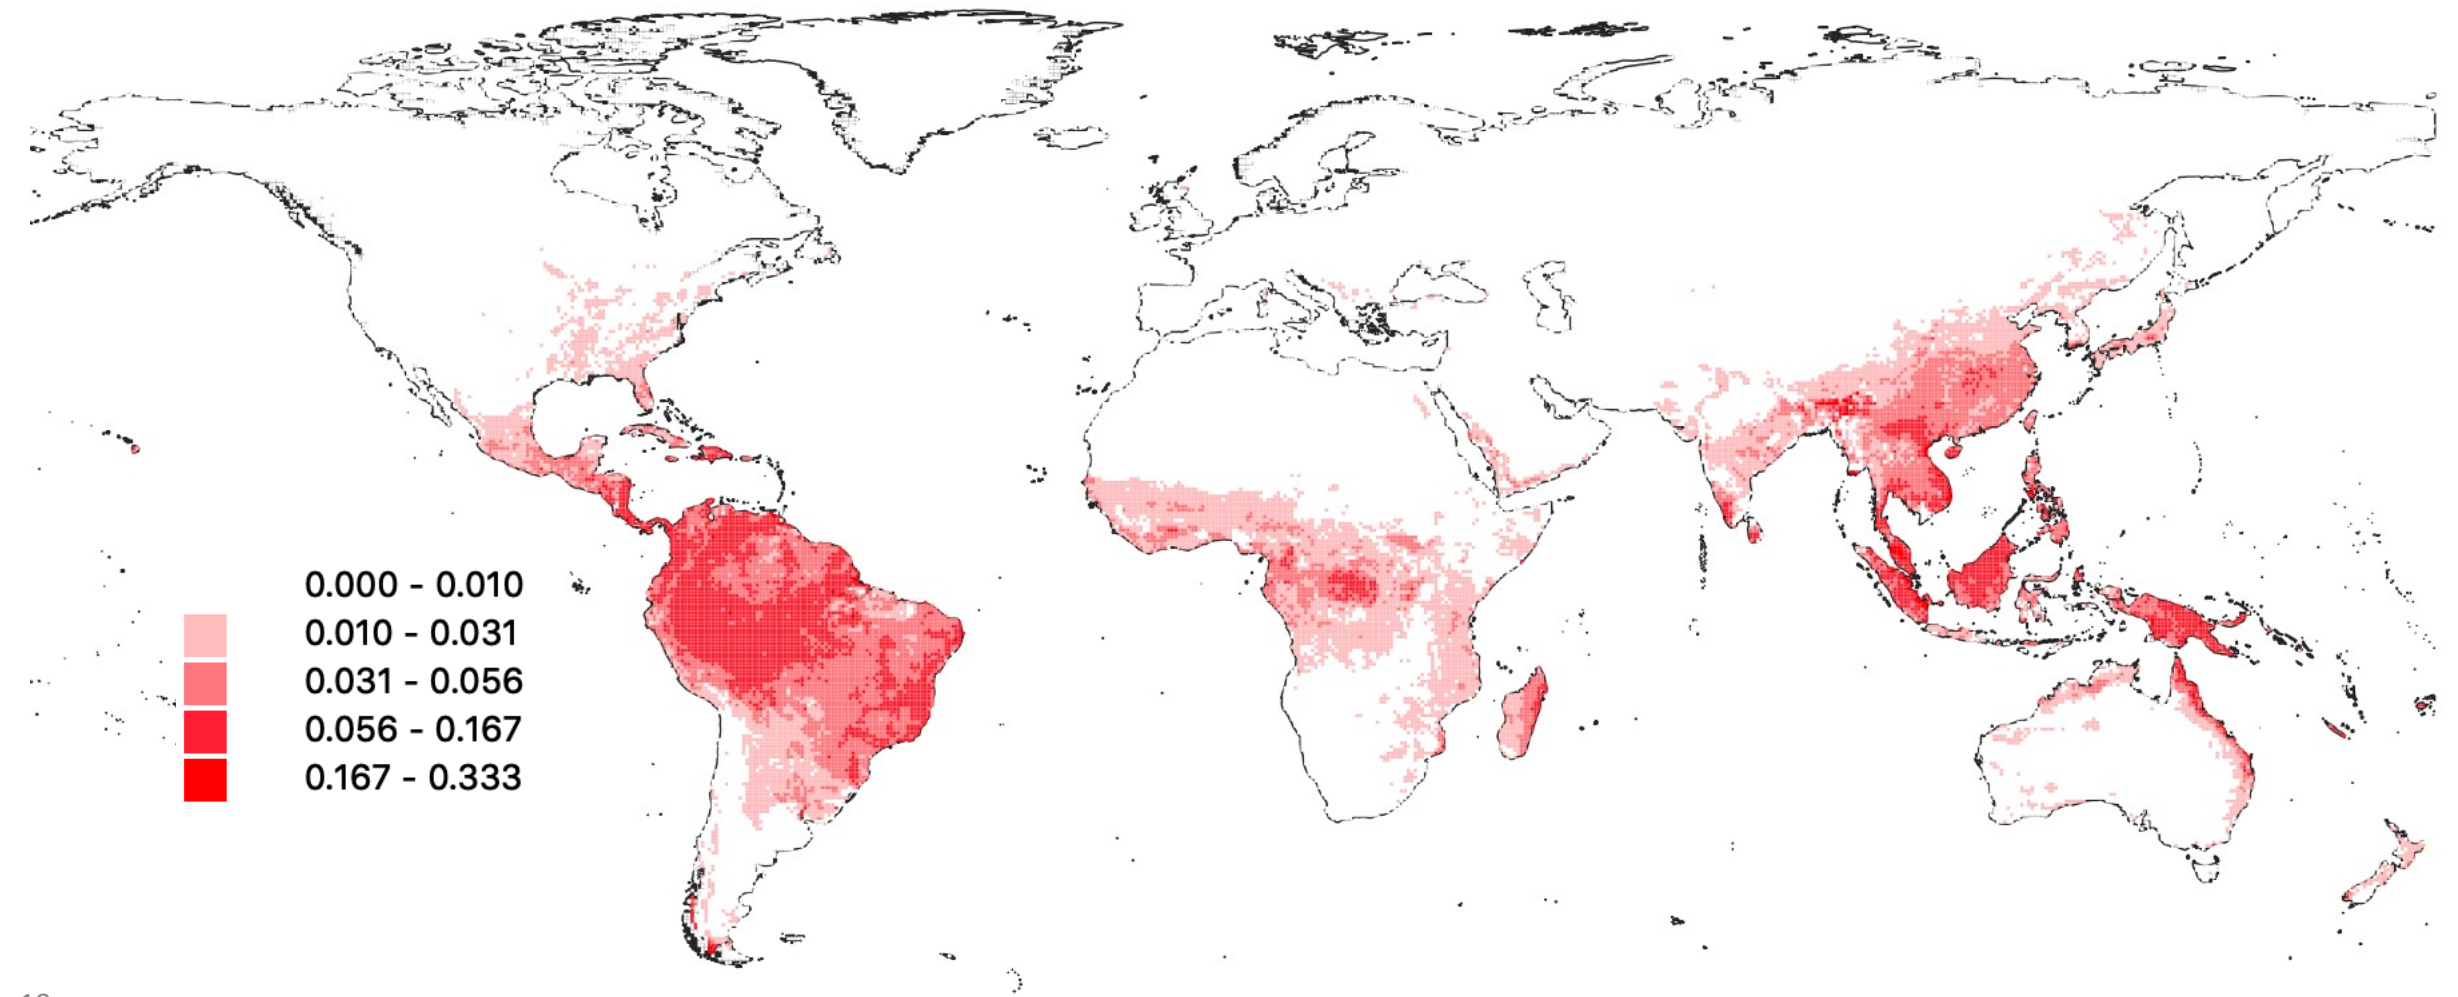

Stamen phyllotaxis

Chloranthoid teeth

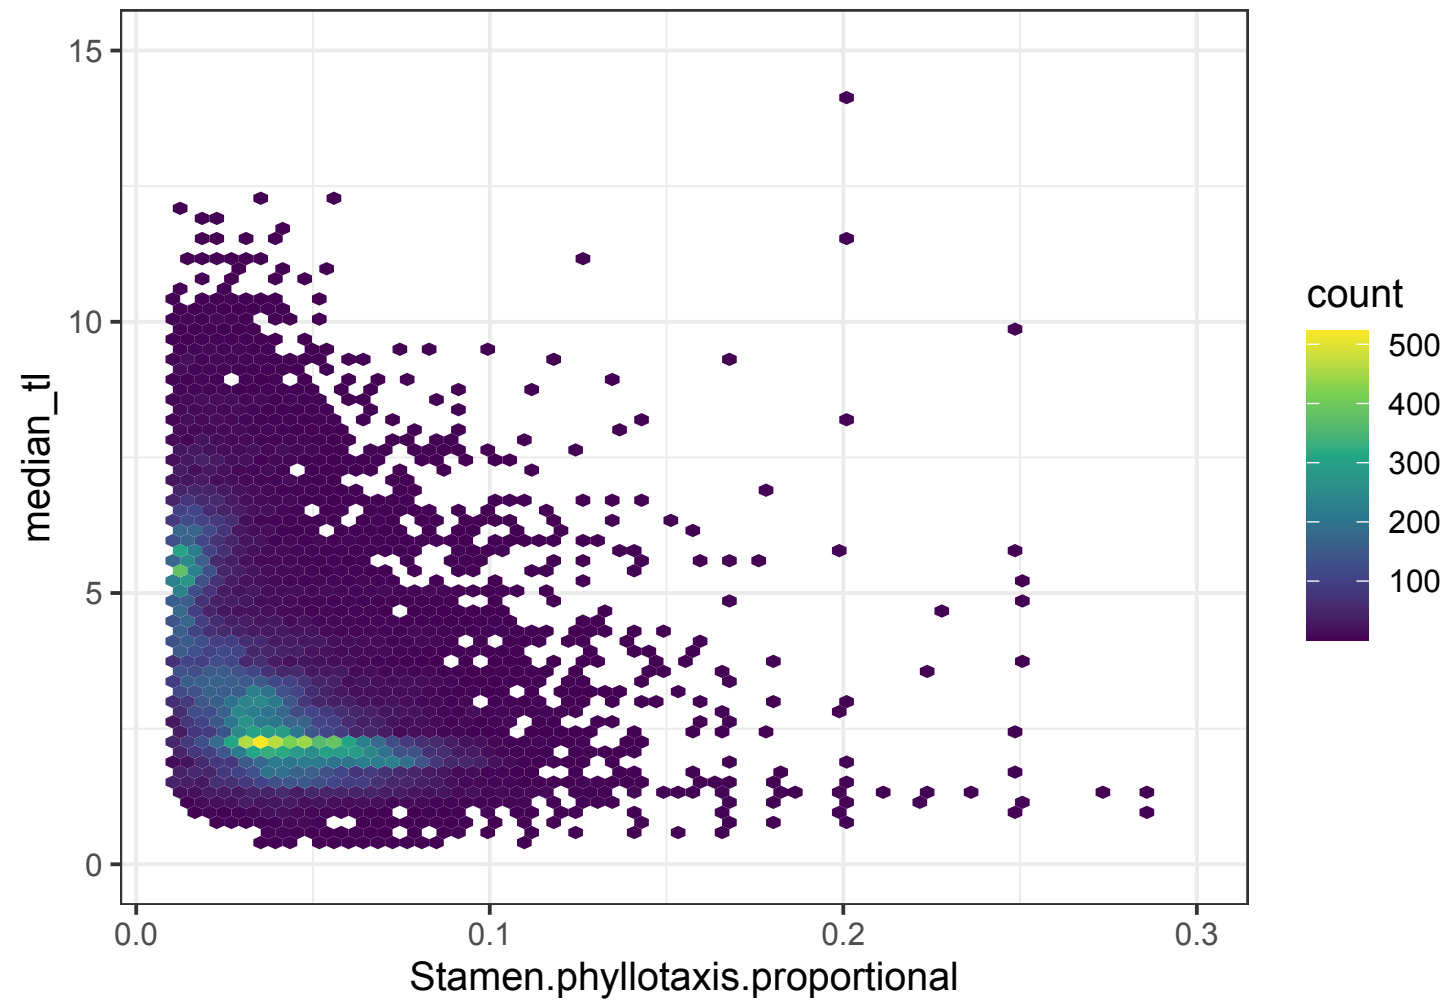

Ethereal oil cells

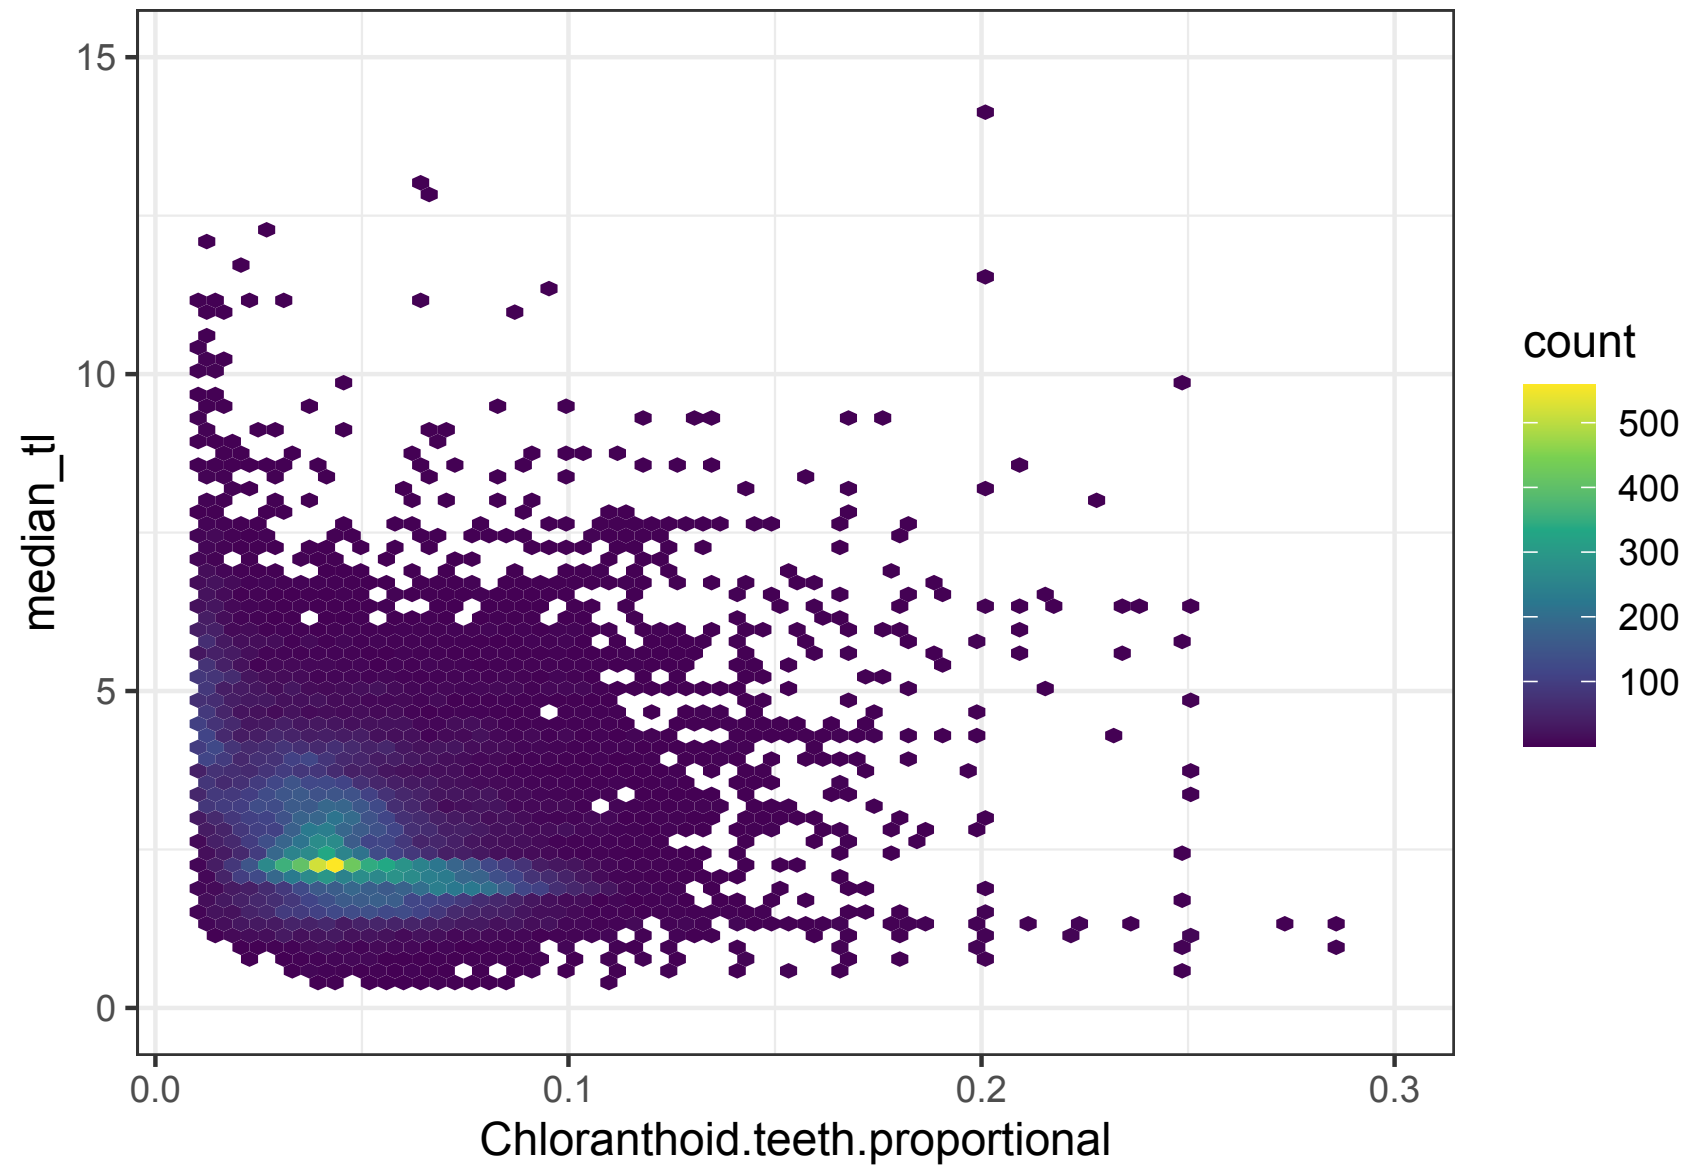

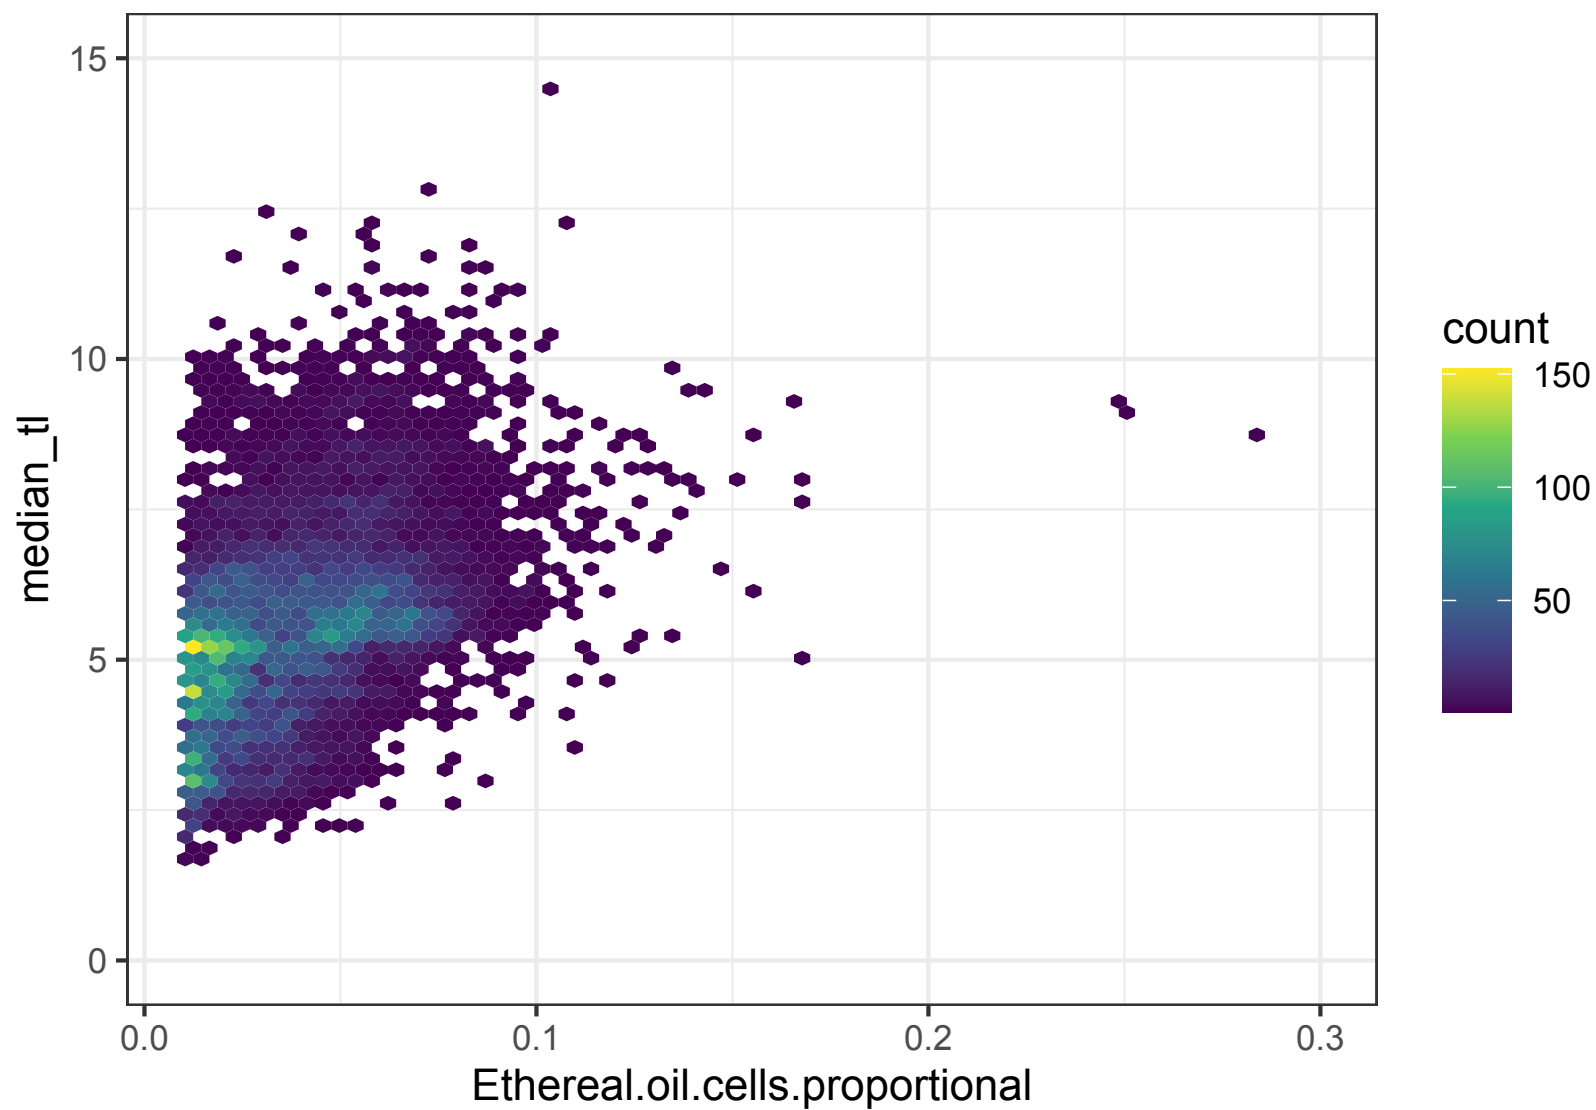

What have we learned?

- Not all traits share the same distribution
- We predicted we could find areas where ancestral traits were concentrated, but we found little concordance among them

More common pattern – reverse of expectation

Opposite pattern – follows expectations

Note – some traits are too rare to produce meaningful plots

Model fitting

- Put grid cells in a model fitting framework
- Generalized Linear Model
- Focused on tip lengths per reasons from previous slide
 - Treated tip length as response variable
- Seek to identify environmental drivers of community age metrics

Model fitting

- Model of environment – 12 temperature, precipitation, soil predictors, tip length as response
 - Adj. R² 0.663 – good explanatory power
 - Normalized coefficients with intuitive interpretation
 - Positive correlation (associated with older species): precipitation, temperature, elevation
 - Negative correlation (associated with younger species): seasonality, soil fertility
 - Variable importance (absolute value of standardized coefficients): Mean annual temperature → mean annual precipitation → soil predictors

Summary of initial observations

- Trait-based measures that try to capture classic hypotheses
- Traits based measures
 - don't agree:
 - Among themselves
 - With phylogenetic measures of species age
 - Have different environmental correlates

Next steps

- Tease apart differing environmental relationships with measures of community “age” or PD
- Different ways of measuring climate disturbance – investigate central hypothesis of historical climate-trait relationships but for now looks like little relationship
